## Abstract

The development of chronic inflammation in later life (inflammaging), alongside changes in immune cell profiles and impaired pathogen defense (immunosenescence), contribute to health risk. However, these processes have been hypothesized as adaptive remodeling of the immune system in response to accumulating somatic damage. Here we consider a recently developed theoretical framework to understand their relationship: the Brain-Body Energy Conservation model of aging. This model views immunosenescence as part of an energy conserving response to the rising energy expenditure of inflammaging. This response promotes short term survival against somatic damage at the expense of future health risk. For example, naïve T cells, which enhance defense against future infections, decline with age, while proteins that suppress the immune response to infection, including IL-10, increase. GDF-15, which is produced in response to chronic inflammation and metabolic stress, and similarly suppresses the immune response to infection, also increases with age. We find evidence consistent with this model in the US Health and Retirement Study (HRS, n = 8,184) and UK Biobank (UKB, n = 40,510). Across both cohorts, the key inflammaging marker TNFR1 partially mediated the age-related increases in IL-10 and GDF-15. In the HRS flow cytometry data, TNFR1 also mediated age-related decreases in naïve T cells. Finally, we assessed vulnerability to a novel future infection using the UKB medical records data on hospitalization or death from COVID-19 (n = 586 hospitalized or died). TNFR1, IL-10, and GDF-15, measured pre-pandemic, all partially mediated the age-related increased risk.

## Keywords:

COVID-19, Inflammation, Biology of Aging, T-cells, GDF-15

## Introduction

Later life is accompanied by complex changes in immune function that are implicated in health risk. There is a pronounced decline in adaptive immunity, which has been referred to as immunosenescence. This is reflected for example in the involution of the thymus and resulting decline in naïve T cells, which play an important role in defense against novel infectious exposures (1-3). Later life is also accompanied by the development of chronic, systemic, and sterile inflammation, termed inflammaging (1, 4). While these changes are often interpreted as immune dysfunction that contributes to aging and disease, some have proposed that they at least partly reflect immune remodeling that “makes the best of a bad situation” (1, 5).

A new theoretical model provides a framework to understand the relationship between inflammaging and immunosenescence from the perspective of adaptive remodeling: the Brain-Body Energy Conservation (BEC) model of aging (6). The BEC model highlights the energetic cost of inflammaging, which is progressively activated in response to accumulating somatic damage. However, total and basal energy expenditure in late life does not increase, instead decreasing after 60 years (7). The suite of functional declines and tissue atrophy observed in later life, including immunosenescence, are therefore viewed as energy conserving responses.

Current evidence suggests inflammaging is energetically costly. For example, cellular injury over time can lead to the development and accumulation of senescent cells throughout the body. These cells have arrested cell division, yet they are continually active. Their pro-inflammatory signaling, termed the senescence-associated secretory profile (SASP) (8), is a major contributor to inflammaging. These cells display markers of increased energy expenditure, such as greater mitochondrial density (6).

1  
2  
3 The BEC model draws from evolutionary life history theory (LHT), which seeks to  
4 understand how organisms allocate their finite resources, including energy, between competing  
5 functions to maximize survival and reproduction (9, 10). Central to LHT is the concept of trade-  
6 offs, as energy invested in one function comes at the expense of another. These trade-offs are  
7 often studied between three broad categories of growth, reproduction, and maintenance, with  
8 immune function considered part of maintenance (9, 11, 12). However, there is also evidence for  
9 potential trade-offs occurring within different components of the immune system, as each comes  
10 with different costs and benefits (10). Innate immunity provides non-specific and fast-acting  
11 defense against cellular damage, and its activation is a central component of inflammaging. In  
12 contrast, adaptive immunity primarily provides enhanced future protection against infections.  
13 This occurs through the proliferation and development of naïve T cells, which can respond to  
14 novel pathogens and develop memory for improved future defense (10). As a result, much of  
15 adaptive immunity provides little immediate survival benefit, suggesting it would be one of the  
16 first functions to be divested from with accumulating energy expenditure from inflammaging.

34

35 Here we test the BEC model linking inflammaging to immunosenescence using data from  
36 two large human cohorts: The US Health and Retirement Study (HRS) and the UK Biobank  
37 (UKB). The HRS is a nationally representative study of US older adults, which provides publicly  
38 available data including several thousand individuals with measured cytokines and naïve T cells.  
39 We used naïve T cell counts as a proxy for investment in the immune repertoire, which decline  
40 with thymus involution in later life. We also used the cytokines interleukin (IL)-6 and soluble  
41 tumor necrosis factor receptor 1 (TNFR1), which are important orchestrators of inflammaging  
42 and are part of the SASP signaling (13, 14). We assessed whether IL-6 and TNFR1 mediated  
43 inverse associations between age and naïve T cells. We also assessed whether these cytokines

3 mediated inverse associations between a collection of chronic diseases, which reflect greater  
4 somatic damage and inflammaging, and naïve T cells. This included hypertension or  
5  
6 cardiovascular disease (CVD), diabetes, and cancer.  
7  
8  
9

10 An expected cost of the trade-off between inflammaging and immunosenescence is  
11 impaired defense against novel infections. To assess this possibility, we relied on the UKB,  
12 which contains cytokine measures in a large sample (approximately 54,000 individuals) at  
13 baseline (years 2006-2010) as well as tracking of COVID-19 hospitalizations or deaths (years  
14 2020-2024). This natural experiment allowed us to test whether greater inflammaging  
15 prospectively predicted greater vulnerability to a novel infection in the future. The proteomics  
16 data from the UKB contains IL-6 and TNFR1 to directly compare with the HRS as well as other  
17 central orchestrators of inflammaging: IL-1 $\beta$  and TNF- $\alpha$ . We assessed whether these cytokines  
18 mediated positive associations between age and hospitalization or death from COVID-19 over  
19 follow up. Similar to the HRS study, we also assessed whether these cytokines mediated positive  
20 associations between chronic diseases and hospitalization or death.

35 It has been noted previously that inflammation “activates many components of dormancy  
36 programs typically induced by nutrient scarcity” (15). Current evidence suggests GDF-15 is an  
37 important mechanism in this process. GDF-15 signals metabolic stress and plays a role in  
38 immune suppression or tolerance in response to chronic inflammation, potentially increasing  
39 vulnerability to novel viral infections like COVID-19 (6, 16-20). Measures of GDF-15 were  
40 available in both the HRS and UKB. We therefore tested whether the pro-inflammatory  
41 cytokines mediated age and disease-related increases in GDF-15, while also testing whether  
42 GDF-15 mediated associations between pro-inflammatory cytokines and COVID-19 health risk  
43 in the UKB.

1  
2  
3 Finally, while increased pro-inflammatory signaling has been observed with age,  
4 increased anti-inflammatory signaling has also been observed across diverse human populations  
5 (21, 22). There are multiple possible reasons for the development of what has been termed anti-  
6 inflammaging (13, 23). Although anti-inflammatory signaling is generally considered protective  
7 for health, there is also evidence that it reinforces inflammaging-driven immunosenescence. An  
8 experimental study in mice found that the anti-inflammatory cytokine IL-10 increased  
9 systemically in response to increasing IL-6 with age and was mechanistically involved in  
10 suppressing the immune response (24). In addition, IL-10 has been found to exert its anti-  
11 inflammatory effects through metabolic reprogramming of macrophages (25), fitting with an  
12 energy conservation framework. We therefore tested whether the pro-inflammatory cytokines  
13 mediated age and disease-related increases in IL-10, while also testing whether GDF-15  
14 mediated associations between pro-inflammatory cytokines and COVID-19 health risk in the  
15 UKB.

## 35 **Methods**

### 36 *US Health and Retirement Study (HRS) sample*

37  
38 The HRS is a nationally representative study of US older adults. Here we focus on the  
39 2016 cross-section that included a venous blood study (26). Participants self-reported whether  
40 they had received a diagnosis of hypertension, a heart condition (cardiovascular disease),  
41 diabetes, or cancer (excluding non-melanoma skin). Participants also reported if their cancer was  
42 improving or going into remission, got worse, or stayed the same. We excluded reports of cancer  
43 improving or going into remission from the cancer designation. Measurement of cytokines and  
44 naïve T cells have been described previously (27, 28). Briefly, IL-6, TNFR1, IL-10, and GDF-15  
45

1  
2  
3 were measured in serum with the Simple Plex assays on the ELLA System (27). Naïve T cells  
4  
5 were measured using flow cytometry from whole blood samples collected in participants' homes.  
6  
7 Blood samples were shipped to the University of Minnesota and processed within 48 hours of  
8  
9 collection. Samples were centrifuged to obtain peripheral blood mononuclear cells (PBMCs),  
10  
11 which were then cryopreserved in liquid nitrogen. Flow cytometry was performed on thawed  
12  
13 PBMC samples using either an LSR II flow cytometer or a Fortessa X20 instrument (BD  
14  
15 Biosciences, San Diego, CA). Immunophenotyping data were analyzed using OpenCyto and  
16  
17 FlowAnnotator. Naïve CD4T and CD8T cells were identified using the following markers:  
18  
19 CD3+ CD19- CD8- CD4+ CD45RA+ CCR7+ CD28+ and CD3+ CD19- CD8+ CD4-  
20  
21 CD45RA+ CCR7+ CD28+. Counts of naïve T cells per milliliter of peripheral blood were  
22  
23 obtained by multiplying the lymphocyte count by the percentage naïve T cells. Lymphocyte  
24  
25 counts were obtained from a differential white blood cell count in an EDTA blood sample  
26  
27 collected simultaneously and a Sysmex XE-2100 instrument (Sysmex America, Inc.,  
28  
29 Lincolnshire, IL) (28, 29). We also considered CMV infection as a potential confounder in the  
30  
31 analysis, which was indicated by the detection of IgG antibodies to CMV, measured in serum  
32  
33 with the Roche e411 immunoassay analyzer (28).

#### 42 *UK Biobank (UKB) sample*

43  
44 The UKB is a large population-based study of health that began with the recruitment of  
45  
46 approximately 500,000 participants across the UK from 2006-2010. Participants self-reported  
47  
48 whether they had hypertension, cardiovascular disease, diabetes, or cancer. They also self-  
49  
50 reported the type of cancer, here we excluded non-melanoma skin cancer from the cancer  
51  
52 designation for consistency with the US HRS. In sensitivity analyses, we also excluded UKB  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 participants who reported lymphoma ( $n = 101$ ), given its potential influence on leukocyte  
4 profiles; however, results were similar and we therefore included them in the analysis.  
5  
6

7  
8 Cytokines were measured in a subsample through proteomic profiling of blood plasma  
9 samples with the antibody-based Olink Explore 3072 PEA (30). This assay includes binding  
10 antibodies to measure 2,923 proteins. Measures reflect relative protein abundance in the sample,  
11 which were rank normalized by UKB researchers, resulting in approximately normal  
12 distributions. We focused on IL-6, TNFR1, IL-10, and GDF-15 to match the available HRS  
13 measures. In addition, we included IL-1 $\beta$  and TNF- $\alpha$ , which are commonly measured cytokines  
14 that play central roles initiating the inflammatory response. Hospitalization or death from  
15 COVID-19 from January 2020 through April 2024 was recorded using hospital and death  
16 records. We specifically focused on cases in which COVID-19 was recorded as the primary  
17 diagnosis or cause of death.

### 31 *Analysis*

32  
33 To rule out potential confounding by acute infection, we excluded individuals with  
34 leukocytosis in both cohorts, using  $>11,000$  leukocytes per microliter ( $\mu\text{L}$ ) of blood as a cutoff.  
35 This excluded 2.87% of the HRS sample and 2.37% of the UKB. In addition, UKB participants  
36 who had died prior to January 1, 2020 (6.9%) or who were lost to follow-up (0.3%) were  
37 excluded from the analysis. This resulted in final sample sizes of  $n = 8,184$  for the HRS and  $n =$   
38  $40,510$  for the UKB. Within the UKB sample,  $n = 586$  were either hospitalized or died from  
39 COVID-19 ( $n = 524$  hospitalizations,  $n = 169$  deaths).  
40

42  
43  
44  
45  
46  
47  
48  
49  
50

51 In the HRS, cytokines were natural log-transformed due to positive skew. Naïve CD4T  
52 and CD8T cell counts were also positively skewed and natural log-transformed after a positive  
53  
54  
55  
56  
57  
58  
59

1  
2  
3 offset (+1) to adjust for zero values. UKB cytokine measures were approximately normally  
4 distributed due to previous rank normalization by UKB researchers and therefore not log-  
5 transformed. Cytokines in both cohorts, as well as naïve T cells, were then standardized (mean =  
6 0, SD = 1).  
7  
8  
9  
10

11 We used linear regression models for predicting continuous outcomes, including naïve T  
12 cells in the HRS and cytokines in both cohorts, as well as logistic regression models for  
13 predicting the dichotomous outcome of hospitalization or death from COVID-19 in the UKB.  
14 Since the HRS is a nationally representative sample, we used the sample weights specific to the  
15 2016 venous blood study. Finally, to account for potential outliers with high leverage resulting in  
16 biased regression coefficients, we used robust regression weighting. This method applies lower  
17 weights to high residual observations, limiting their influence (31). As a result, model  
18 coefficients are more robust to outliers with high leverage. The code used in the analysis can be  
19 found at: [https://github.com/jakearonoff/hrs\\_ukb\\_immuneaging](https://github.com/jakearonoff/hrs_ukb_immuneaging).

## 35 Results

36 The UKB sample was substantially larger, while the HRS sample was older and had a  
37 higher prevalence of disease at the time of cytokine measurement (**Table 1**). In both cohorts,  
38 there were slightly more women than men. Distributions for cytokines and naïve T cells in the  
39 HRS are shown in **Supplementary Figures S1-3**. This includes the skewed raw data and the  
40 approximately normal distribution after log-transformation. Approximately normal distributions  
41 of the UKB cytokine measures are shown in **Supplementary Figure S4**. All cytokines were  
42 positively correlated across both the HRS and UKB (**Supplementary Tables S1-2**). In both  
43 cohorts, age and disease were positively associated with pro-inflammatory cytokines, with the

10 *Age, disease, cytokines, and naïve T cells in the HRS*

11  
12 Regression models showing associations between age, diseases, cytokines, and naïve T  
13 cells in the HRS are shown in **Table 2**. An increase of 1 year in age was associated with a 0.013  
14 and 0.051 SD increase in IL-10 and GDF-15 respectively, as well as a 0.014 and 0.026 decrease  
15 in naïve CD4T and CD8T cells respectively. Male sex was associated with a 0.091 and 0.154 SD  
16 increase in IL-10 and GDF-15 respectively, as well as a 0.359 and 0.218 SD decrease in naïve  
17 CD4T and CD8T respectively. Having hypertension or CVD was associated with a 0.171 and  
18 0.231 SD increase in IL-10 and GDF-15 respectively, as well as a 0.097 SD decrease in naïve  
19 CD4T cells. Having diabetes was associated with a 0.246 and 0.505 SD increase in IL-10 and  
20 GDF-15 respectively, as well as a 0.090 SD decrease in naïve CD4T cells. Having cancer was  
21 associated with a 0.074 SD increase in IL-10, as well as a 0.216 and 0.088 SD decrease in naïve  
22 CD4T and CD8T cells respectively.

#### 14 *Age, disease, cytokines, and COVID-19 health risk in the UKB*

15  
16  
17 Regression models showing associations between age, diseases, cytokines, and COVID-  
18  
19 19 hospitalization or death in the UKB are shown in **Table 3**. One year increase in age was  
20  
21 associated with a 0.002 and 0.051 SD increase in IL-10 and GDF-15 respectively, as well as 6%  
22  
23 increased odds of hospitalization or death from COVID-19. Male sex was not associated with IL-  
24  
25 10; however, it was associated with a 0.159 SD increase in GDF-15 and 23% increased odds of  
26  
27 hospitalization or death from COVID-19. Having hypertension or CVD was associated with a  
28  
29 0.036 and 0.192 SD increase in IL-10 and GDF-15 respectively, as well as 53% increased odds  
30  
31 of hospitalization or death from COVID-19. Diabetes was associated with a 0.143 and 0.978 SD  
32  
33 increase in IL-10 and GDF-15 respectively, as well as 106% increased odds of hospitalization or  
34  
35 death from COVID-19. Cancer was associated with a 0.066 and 0.084 SD increase in IL-10 and  
36  
37 GDF-15 respectively. While not statistically significant, cancer was associated with 14%  
38  
39 increased odds of hospitalization or death from COVID-19.  
40  
41  
42  
43  
44

45 IL-6, TNFR1, and TNF- $\alpha$  were all positively associated with IL-10, GDF-15, and odds of  
46  
47 hospitalization or death from COVID-19 (cytokines measured pre-pandemic), while their  
48  
49 addition to the models attenuated positive associations for age, cardiometabolic disease, and  
50  
51 cancer. IL-10 and GDF-15 were positively associated with odds of hospitalization or death from  
52  
53 COVID-19 (IL-10 at  $p < 0.10$ ), while their addition to the model attenuated positive associations

13  
14  
15  
16

### 17 *Additional models and sensitivity analyses*

18  
19 We considered additional measures and models to assess potential confounding and  
20 interactions. This included weight (kg), a proxy for energy expenditure, as individual differences  
21 might confound energy conservation responses. In addition, associations for naïve T cells and  
22 COVID-19 health risk could be confounded by individual differences in cellular proliferative  
23 capacity, which declines with age and disease but is not part of a hypothesized energy  
24 conservation response. We relied on red blood cells and platelets as proxies for this possible  
25 confounding. Finally, we considered CMV infection in the HRS models as another potential  
26 confounder, since it increases pro-inflammatory cytokines and decreases naïve T cells (32).  
27  
28 Approximately normal distributions for weight, red blood cells, and platelets in both cohorts are  
29 shown in **Supplementary Figures S5-6**. Results were very similar after adding these variables to  
30 the models, including CMV infection in the HRS models, suggesting minimal or no confounding  
31  
32  
33  
34

42  
43  
44  
45 **(Supplementary Tables S4-5)**.

46  
47 Since total and basal energy expenditure have been found to decrease in later life, we  
48 considered whether the hypothesized energy conservation response intensified with age using  
49 interaction terms. These were mostly null, while significant age interaction terms were not  
50 consistent in direction. For example, in the HRS, the positive association between cancer and IL-  
51

1  
2  
3 10 was stronger at older ages, however the negative association between cancer and naïve CD4T  
4 cells attenuated (**Supplementary Tables S6**). Further, the inverse association between TNFR1  
5 and naïve CD8T cells attenuated with older age. In the UKB, the positive association between  
6 TNFR1 and GDF-15 strengthened with older age, while the positive association between IL-6  
7 and GDF-15 weakened (**Supplementary Tables S7**). Associations between cytokines and  
8 COVID-19 hospitalization or death risk were not modified by age.  
9

12  
13  
14  
15  
16  
17 While GDF-15 does not directly induce thymus involution and resulting decline in naïve  
18 T cells, it serves as a proxy for metabolic stress in response to inflammation. Therefore, as an  
19 additional test of the energy conservation model, we tested associations between GDF-15 and  
20 naïve T cells in the HRS. GDF-15 was inversely associated with both naïve CD4T and CD8T  
21 cells (**Supplementary Table S8**). Further, GDF-15 attenuated inverse associations between age  
22 and naïve CD4T and CD8T cells, cardiometabolic disease and naïve CD4T cells, as well as  
23 cancer and naïve CD4T and CD8T cells.

31  
32  
33 Since risk of hospitalization or death from COVID-19 could be due to a combination of  
34 an energy conservation response as well as dysfunctional immunity, we considered a sensitivity  
35 analysis excluding individuals with diseases or conditions related to dysregulated inflammation.  
36 We excluded individuals with hypertension or CVD, diabetes, and cancer, as well as those with  
37 COPD, asthma, or allergies. This resulted in a subsample of 17,613 in which 162 were later  
38 hospitalized or died from COVID-19 (**Supplementary Table S9**). In this subsample analysis,  
39 associations for IL-6 and TNF- $\alpha$  attenuated, while associations for TNFR1 and IL-10  
40 strengthened. The positive association between GDF-15 and odds of hospitalization or death was  
41 nearly identical in comparing the healthier subsample with the full sample.

### *HRS mediations among age and disease, cytokines, and naïve T cells*

HRS mediation paths are shown in **Figure 1** and **Supplementary Table S10**, determined by the attenuation of the predictor-outcome association after adding the mediator. The positive association between age and IL-10 was mediated 81% by TNFR1. The positive association between age and GDF-15 was mediated 32% by TNFR1 and IL-6 together. However, individual mediation paths revealed this was primarily attributable to TNFR1, which mediated 28% of the age association independent of IL-6, while IL-6 only mediated 1% of the age association independent of TNFR1 (**Supplementary Table S10**). The inverse association between age and naïve CD4T cells was mediated 19% by TNFR1 and IL-6 together. However, this was mostly attributable to TNFR1, which mediated 12% of the age association independent of IL-6, while IL-6 only mediated 2% of the age association independent of TNFR1. TNFR1 mediated 4% of the inverse association between age and naïve CD8T cells.

The positive association between hypertension or CVD and IL-10 was mediated 90% by TNFR1 and IL-6 together, while for single paths TNFR1 mediated 80% of the association after adjusting for IL-6 and IL-6 mediated 66% of the association after adjusting for TNFR1 (**Supplementary Table S10**). The positive association between hypertension or CVD and GDF-15 was mediated 53% by TNFR1 and IL-6 together, while for single paths TNFR1 mediated 41% of the association after adjusting for IL-6 and IL-6 mediated 8% of the association after adjusting for TNFR1. The inverse association between hypertension or CVD and naïve CD4T cells was mediated 35% by TNFR1 and IL-6 together, while for single paths TNFR1 mediated 18% of the association after adjusting for IL-6 and IL-6 mediated 12% of the association after adjusting for TNFR1.

1  
2  
3 The positive association between diabetes and IL-10 was mediated 59% by TNFR1 and  
4 IL-6 together, while for single paths TNFR1 mediated 47% of the association after adjusting for  
5 IL-6 and IL-6 mediated 11% of the association after adjusting for TNFR1. The positive  
6  
7  
8 association between diabetes and GDF-15 was mediated 33% by TNFR1 and IL-6 together,  
9  
10 while for single paths TNFR1 mediated 24% of the association after adjusting for IL-6 and IL-6  
11  
12 mediated 4% of the association after adjusting for TNFR1. The inverse association between  
13  
14  
15 diabetes and naïve CD4T cells was mediated 37% by TNFR1 and IL-6 together, while for single  
16  
17  
18 paths TNFR1 mediated 25% of the association after adjusting for IL-6 and IL-6 mediated 7% of  
19  
20  
21 the association after adjusting for TNFR1.  
22

23  
24 The positive association between cancer and IL-10 was mediated 28% by TNFR1, while  
25  
26 the negative associations with naïve CD4T and CD8T cells were mediated 3% and 6% by  
27  
28 TNFR1 respectively. Although cancer was positively associated with GDF-15 at  $p < 0.10$  after  
29  
30 adjusting for IL-6 and TNFR1, they did not mediate the association.  
31  
32

### 33 34 35 *UKB mediations among age and disease, cytokines, and COVID-19 health risk*

36  
37  
38 UKB mediation paths are shown in **Figure 2** and **Supplementary Tables S11-12**. The  
39  
40 positive association between age and IL-10 was mediated 100% by TNFR1, TNF- $\alpha$ , and IL-6  
41  
42 together. It was not possible to estimate independent mediation paths due to the strong  
43  
44 associations. For example, adding either TNFR1 or TNF- $\alpha$  alone into the model completely  
45  
46 attenuated the positive association between age and IL-10. The positive association between age  
47  
48 and GDF-15 was mediated 23% by TNFR1, TNF- $\alpha$ , and IL-6 together, while adjusting for each  
49  
50 cytokine indicated single paths of 10%, 1%, and 2% for TNFR1, TNF- $\alpha$ , and IL-6 respectively.  
51  
52  
53 The positive association between age and odds of hospitalization or death from COVID-19 was  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 mediated 26% by TNFR1, TNF- $\alpha$ , and IL-6 together, while adjusting for each cytokine indicated  
4  
5 single paths of 19%, 1%, and 5% for TNFR1, TNF- $\alpha$ , and IL-6 respectively.  
6  
7

8 The positive association between hypertension or CVD and IL-10 was mediated 100% by  
9  
10 TNFR1, TNF- $\alpha$ , and IL-6. Similar to the age association, it was not possible to estimate  
11  
12 independent mediation paths due to the strong associations. The positive association between  
13  
14 hypertension or CVD and GDF-15 was mediated 52% by TNFR1, TNF- $\alpha$ , and IL-6 together,  
15  
16 while adjusting for each cytokine indicated single paths of 25%, 2%, and 13% for TNFR1, TNF-  
17  
18  $\alpha$ , and IL-6 respectively. The positive association between hypertension or CVD and odds of  
19  
20 hospitalization or death from COVID-19 was mediated 34% by TNFR1 and IL-6 together, while  
21  
22 adjusting for each cytokine indicated single paths of 24% and 5% for TNFR1 and IL-6  
23  
24 respectively.  
25  
26  
27  
28

29 The positive association between diabetes and IL-10 was mediated 56% by TNFR1,  
30  
31 TNF- $\alpha$ , and IL-6 together, while adjusting for each cytokine indicated single paths of 16%, 7%  
32  
33 and 3% for TNFR1, TNF- $\alpha$ , and IL-6 respectively. The positive association between diabetes  
34  
35 and GDF-15 was mediated 15% by TNFR1, TNF- $\alpha$ , and IL-6 together, while adjusting for each  
36  
37 cytokine indicated single paths of 12%, 1%, and 3% for TNFR1, TNF- $\alpha$ , and IL-6 respectively.  
38  
39 The positive association between diabetes and odds of hospitalization or death from COVID-19  
40  
41 was mediated 32% by TNFR1 and IL-6 together, while adjusting for each cytokine indicated  
42  
43 single paths of 27% and 3% for TNFR1 and IL-6 respectively.  
44  
45  
46  
47

48 TNFR1 mediated 7% of the positive association between cancer and IL-10 independent  
49  
50 of other cytokines, while IL-6 also mediated 3% of the association independent of other  
51  
52 cytokines. Similarly, TNFR1 mediated 35% of the positive association between cancer and GDF-  
53  
54 15 independent of other cytokines, while IL-6 also mediated 12% of the association independent  
55  
56  
57  
58  
59  
60

1  
2  
3 of other cytokines. Since cancer was positively but not statistically significantly associated with  
4 odds of hospitalization or death from COVID-19, we did not consider mediation paths.  
5  
6

7  
8 The positive association between TNFR1 and odds of hospitalization or death from  
9 COVID-19 was mediated 38% by IL-10 and GDF-15, while adjusting for each cytokine  
10 indicated single paths of 4% and 39% for IL-10 and GDF-15 respectively. The positive  
11 association between TNF- $\alpha$  and odds of hospitalization or death from COVID-19 was mediated  
12 27% by IL-10 and GDF-15, while adjusting for each cytokine indicated single paths of 15% and  
13 16% for IL-10 and GDF-15 respectively. The positive association between IL-6 and odds of  
14 hospitalization or death from COVID-19 was mediated 16% by IL-10 and GDF-15, while  
15 adjusting for each cytokine indicated single paths of 1% and 8% for IL-10 and GDF-15  
16 respectively.

19  
20  
21  
22  
23  
24  
25  
26  
27

28  
29 GDF-15 also mediated associations independent of the pro-inflammatory cytokines  
30 TNFR1, TNF- $\alpha$ , and IL-6. This included age, in which GDF-15 mediated 18% of the positive  
31 association with odds of hospitalization or death from COVID-19. In addition, GDF-15 mediated  
32 16% and 45% of the positive associations for hypertension or CVD and diabetes respectively,  
33 independent of TNFR1, TNF- $\alpha$ , and IL-6.

### 43 **Discussion**

44  
45 Here we found evidence in two large human cohorts that is consistent with an energy  
46 conservation model of inflammaging and immunosenescence. TNFR1, an indicator of  
47 inflammaging, was inversely associated with naïve T cells in the HRS, positively associated with  
48 odds of hospitalization or death from COVID-19 in the UKB, and mediated the associations  
49 between older age and these outcomes (12% for CD4T, 4% for CD8T, 19% for COVID-19). We  
50

54  
55  
56  
57  
58  
59  
60

1  
2  
3 also found evidence consistent with the role of anti-inflammaging in augmenting  
4 immunosenescence in response to inflammaging. The anti-inflammatory cytokine IL-10 was  
5 positively associated with odds of hospitalization or death from COVID-19 and mediated 4% of  
6 the TNFR1 association. Finally, in further support of the energy conservation model of immune  
7 aging, GDF15, which is elevated in response to chronic inflammation and contributes to immune  
8 tolerance, also mediated 39% of the association between TNFR1 and increased risk of  
9 hospitalization or death, as well as 18% of the age-related increased risk independent of TNFR1.

10  
11 Our findings are consistent with multiple previous studies on inflammation and immune  
12 function. For example, in the Multi-Ethnic Study of Atherosclerosis (MESA), both subclinical  
13 atherosclerosis and IL-6 were inversely associated with naïve CD4T cells (33). Another study of  
14 older individuals also found an inverse association between IL-6 and naïve T cells (34). Further,  
15 both subclinical atherosclerosis and elevated C-Reactive Protein (CRP), a marker of chronic low-  
16 grade inflammation, were found to be inversely associated with the inflammatory response to  
17 vaccination (35, 36). Further, CRP has also been found to be inversely associated with the  
18 antibody response to vaccination (37).

19  
20 Adaptive remodeling in later life to promote short term survival raises the question of  
21 how this response would evolve with diminishing selection pressure. One potential explanation  
22 is that this energy conservation response evolved to function during acute periods of somatic  
23 damage in early life. An example of this is acute or transient thymus involution, which can be  
24 induced by a variety of exposures inducing somatic damage or energetic stress (e.g.,  
25 chemotherapy, infection, malnutrition, pregnancy) (38, 39). There is also evidence that several  
26 cytokines play a role in acute thymus involution, including the ones examined here (38, 39). This  
27 acute response could have plausibly been co-opted for later life. Further, while selection pressure  
28

1  
2  
3 wanes, it is not completely absent, and this could further reinforce the energy conservation  
4  
5 response to inflammaging.  
6

7  
8 A key open question is how to empirically distinguish adaptive remodeling from  
9  
10 maladaptive decline in late life (5). Our approach here was to assess how strong the associations  
11  
12 were between age, cytokines, and COVID-19 health risk remained after excluding individuals  
13  
14 with reported inflammatory diseases or conditions. While this approach is admittedly imperfect,  
15  
16 if associations attenuated when individuals with the most dysregulated inflammatory responses  
17  
18 were removed, it would suggest dysregulation was playing a larger role. This appeared to be the  
19  
20 case for IL-6 and TNF- $\alpha$ , which were no longer predictive of COVID-19 health after removing  
21  
22 individuals with inflammatory conditions. In the HRS, IL-6 showed stronger mediation between  
23  
24 diseases and naïve T cells compared to age, further suggesting dysregulated inflammation was  
25  
26 playing a larger role in the IL-6 associations. In contrast, associations for TNFR1 and GDF-15  
27  
28 predicting COVID-19 hospitalization or death in the UKB were very similar after removing  
29  
30 individuals with inflammatory conditions, suggesting potential confounding by dysregulated  
31  
32 inflammation was minimal or absent. Further, the IL-10 association strengthened after removing  
33  
34 these individuals, suggesting that dysregulated immune function was obscuring the relationship  
35  
36 between age-related increases in IL-10 and impaired pathogen defense. In order to assess  
37  
38 potential confounding due to age-related functional decline separate from an expected energy  
39  
40 conservation response, we considered models with red blood cell counts and platelets, which  
41  
42 both decline with age due to declining proliferative capacity. Results were nearly identical in  
43  
44 both the HRS and UKB after adding these variables, suggesting minimal or no confounding.  
45  
46  
47  
48  
49  
50

51  
52 While here we propose that the BEC model can help explain atrophy of the immune  
53  
54 repertoire, it is likely not a comprehensive explanation. With decreasing residual life expectancy,  
55  
56  
57  
58  
59  
60

1  
2  
3 the benefits of investment in the immune repertoire decline. As a result, we should expect  
4 atrophy of the immune repertoire with declining life expectancy, as is the case in later life. This  
5 might explain why we found strong inverse associations between male sex, which is associated  
6 with lower life expectancy, and naïve T cells. Relatedly, most infectious exposures have already  
7 been encountered by later life, and as a result the marginal value of further investment in the  
8 immune repertoire declines. This multifactorial process likely explains why the inflammaging  
9 markers IL-6 and TNFR1 mediated only a small proportion of the association between age and  
10 naïve T cells in the HRS.  
11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21

22 The multifactorial process of functional decline and tissue atrophy across multiple bodily  
23 systems with age could also explain why we generally did not find evidence that the energy  
24 conservation response intensified with age. If the age-related declines in total and basal energy  
25 expenditures are due to functional declines and tissue atrophy from factors independent of an  
26 energy conservation response, this would explain our largely null age interaction terms. If future  
27 studies on other bodily systems similarly find that associations do not intensify with older age,  
28 this would further suggest the multifactorial explanation.  
29  
30  
31  
32  
33  
34  
35  
36  
37

38 Our results for IL-10 are consistent with prior studies suggesting this cytokine plays a  
39 role in augmenting immunosenescence and increased vulnerability to infection in later life (24,  
40 32). However, its influence on disease and aging is complex and context specific. Current  
41 evidence suggests that greater IL-10 is protective from the development of inflammaging and  
42 potentially some inflammatory diseases such as CVD (13, 32, 40). Further, the increase in IL-10  
43 in response to inflammaging might serve multiple functions. In addition to energy conservation,  
44 IL-10 might also play a role in striking a balance between an excessive inflammatory response  
45  
46  
47

59  
60

1  
2  
3 that contributes to aging and disease and an impaired immune response to infections (41, 42).  
4  
5 This might similarly be the case with GDF-15 (43).  
6  
7

8         While here we use the terminology of inflammaging and anti-inflammaging, consistent  
9  
10 with pro- and anti-inflammatory, it is important to note these cytokines likely reflect a single  
11  
12 immune response. Evidence for this can be seen for example in the positive correlations amongst  
13  
14 cytokines with opposing functions reported here and in previous studies, as well as similar  
15  
16 principal component loadings (14, 21, 22).  
17  
18

19         Our findings highlight TNFR1 as a particularly important marker of inflammaging. This  
20  
21 is consistent with a recent study using a battery of cytokines to measure inflammaging across  
22  
23 human populations. At least among industrialized populations, TNFR1 was a strong indicator of  
24  
25 inflammaging (14). In contrast, we found that other markers often used to measure  
26  
27 inflammaging, including IL-6, IL-1 $\beta$ , and TNF- $\alpha$ , showed weaker associations with naïve T cells  
28  
29 or odds of hospitalization or death from COVID-19. These results highlight the importance of  
30  
31 measuring TNFR1 in future studies.  
32  
33  
34

35         This energy conservation model linking inflammaging to immunosenescence has  
36  
37 important health implications. For example, it could offer an explanation of the rapamycin  
38  
39 immune function “paradox”. While rapamycin was originally used as an immunosuppressant for  
40  
41 organ transplant patients, it has been found to improve antibody responses to vaccination as well  
42  
43 as reduce infection risk over follow-up (44, 45). The energy conservation model of immune  
44  
45 aging suggests this effect is likely indirect. Rapamycin can inhibit SASP signaling, thereby  
46  
47 reducing inflammaging (46, 47). As a result, the divestment from the immune repertoire could be  
48  
49 reversed, improving immune responses to novel infectious exposures (48). Relatedly, previous  
50  
51 findings of transient and reversible thymus involution highlighted above further suggests the  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 potential for reversing immunosenescence if inflammaging can be attenuated. This could be  
4 accomplished therapeutically, such as with rapamycin, or through lifestyle changes. For  
5  
6  
7  
8 example, among older adults, physical activity has been found to be inversely associated with IL-  
9  
10 6 and positively associated with naïve CD4T cells (34). Further, non-industrialized human  
11  
12 populations that are highly physically active with minimal excess caloric consumption, such as  
13  
14 Tsimane forager-horticulturalists in the Bolivian Amazon, show markedly attenuated  
15  
16 inflammaging (14, 22). Finally, a horticulture lifestyle intervention showed a reduction in IL-6  
17  
18 and increase in naïve CD8T cells (49). However, it is important to distinguish between  
19  
20 interventions that might artificially dampen inflammaging such as anti-inflammatory  
21  
22 medications and interventions that might address the causes of inflammaging, such as physical  
23  
24 activity. Under the BEC, the former might succeed in reducing immunosenescence only at the  
25  
26 cost of perturbing the complex energetic balance the body is attempting to maintain during  
27  
28  
29  
30  
31 aging.

32  
33 Our study is not without limitations. While we assessed indicators of both investment in  
34  
35 the immune repertoire and an outcome of vulnerability to novel infection, these were measured  
36  
37 in different individuals across the two US and UK cohorts. The two cohorts also differed in  
38  
39 cytokine assay methods. Cytokine measurements were cross-sectional, and as a result we cannot  
40  
41 definitively assess causal ordering. Further, due to the complex signaling network of cytokines  
42  
43 that results in a versatile emergent property of immune function (50), we also cannot rule out  
44  
45 bidirectional causality amongst cytokines. Finally, we did not have direct measures of total or  
46  
47 basal energy expenditure. However, when we assessed results before and after adding body  
48  
49 weight to the models, a proxy for energy expenditure, results were nearly identical, suggesting  
50  
51  
52  
53  
54 this was not a major confounder.

1  
2  
3 In conclusion, here we find evidence consistent with an energy conservation model of  
4 immune aging. Immunosenescence, at least in part, can be understood as an energy conservation  
5 response to rising inflammaging in later life. This response likely promotes short term survival at  
6 the expense of greater vulnerability to novel infections in the future. Considering waning  
7 selection pressure with age, this response likely originally evolved for surviving short term  
8 stressors in early life and has been co-opted to operate chronically in later life. Finally, our study  
9 also highlights the role of anti-inflammatory signaling, or anti-inflammaging, as a contributor to  
10 immunosenescence.

**Table 1.** Descriptive statistics

	<b>HRS (full sample)</b>	<b>HRS (GDF-15 subsample)</b>	<b>UKB</b>
n	8,184	3,791	40,510
Mean age (SD)	68.5 (9.8)	68.4 (9.8)	56.4 (8.2)
Age range	50 – 107	50 – 100	40 – 70
% Male	46.2	45.9	45.0
% with hypertension or CVD	65.2	66.1	29.1
% with diabetes	24.6	24.9	4.8
% with cancer	10.7	9.4	6.0

**Table 2.** Regression models predicting IL-10, GDF-15, and Naïve T cells counts in the US HRS.

Cytokines and T cell counts were standardized, with resulting regression coefficients reflecting changes in standard deviations (n = 8,184 for full sample; n = 3,791 for GDF-15 subsample).

Estimates are reported as  $\beta$  (SE).

	IL-10	IL-10	GDF-15	GDF-15	Naïve CD4T	Naïve CD4T	Naïve CD8T	Naïve CD8T

**Table 3.** Linear regression models predicting IL-10 and GDF-15, as well as logistic regression models predicting odds of hospitalization or death from COVID-19 (n = 586 out of 40,510).

Cytokines were standardized, reflecting changes in standard deviations. Linear regression estimates are reported as  $\beta$  (SE), while logistic regression estimates are reported as odds ratios with 95% confidence intervals.
